# P-Value

*“Statistically speaking, science suffers from an excess of significance.” – Hotz (2007)*

*Q: Why do so many colleges and grad schools teach  $p = 0.05$ ?*

*A: Because that's still what the scientific community and journal editors use.*

*Q: Why do so many people still use  $p = 0.05$ ?*

*A: Because that's what they were taught in college or grad school.*

*– Wasserstein and Lazar (2016)*

## P-Value

- There has been a growing concern about issues of **reproducibility** and **replicability** of scientific conclusions.
- Underpinning many published scientific conclusions is the concept of “statistical significance,” typically assessed with the  $p$ —value.
- While the  $p$ —value can be a useful statistical measure, it is often misinterpreted and its use as a primary maker of scientific discovery in empirical studies can be highly problematic.

Ioannidis, J. P. A. 2005. "Why Most Published Research Findings Are False," *PLoS Medicine*, 2(8).

## Abstract

Go to:

## Summary

There is increasing concern that most current published research findings are false. The probability that a research claim is true may depend on study power and bias, the number of other studies on the same question, and, importantly, the ratio of true to no relationships among the relationships probed in each scientific field. In this framework, a research finding is less likely to be true when the studies conducted in a field are smaller; when effect sizes are smaller; when there is a greater number and lesser preselection of tested relationships; where there is greater flexibility in designs, definitions, outcomes, and analytical modes; when there is greater financial and other interest and prejudice; and when more teams are involved in a scientific field in chase of statistical significance. Simulations show that for most study designs and settings, it is more likely for a research claim to be false than true. Moreover, for many current scientific fields, claimed research findings may often be simply accurate measures of the prevailing bias. In this essay, I discuss the implications of these problems for the conduct and interpretation of research.

## The Statistical Crisis in Science

Andrew Gelman

Columbia University, New York, USA

Top journals in psychology routinely publish ridiculous, scientifically implausible claims, justified based on “ $p < 0.05$ .” And this in turn calls into question all sorts of more plausible, but not necessarily true, claims, that are supported by this same sort of evidence. To put it another way: we can all laugh at studies of ESP, or ovulation and voting, but what about MRI studies of political attitudes, or embodied cognition, or stereotype threat, or, for that matter, the latest potential cancer cure? If we can’t trust p-values, does experimental science involving human variation just have to start over? And what do we do in fields such as political science and economics, where preregistered replication can be difficult or impossible? Can Bayesian inference supply a solution? Maybe. These are not easy problems, but they’re important problems.

## Abandon Statistical Significance

Blakeley B. McShane<sup>a</sup>, David Gal<sup>b</sup>, Andrew Gelman<sup>c</sup>, Christian Robert<sup>d</sup>, and Jennifer L. Tackett<sup>e</sup>

<sup>a</sup> Department of Marketing, Kellogg School of Management, Northwestern University, Evanston, IL; <sup>b</sup> Department of Managerial Studies, College of Business Administration, University of Illinois at Chicago, Chicago, IL; <sup>c</sup> Department of Statistics and Department of Political Science, Columbia University, New York, NY; <sup>d</sup> Centre de Recherche en Mathématiques de la Décision (CEREMADE), Université Paris-Dauphine, Paris, France; <sup>e</sup> Department of Psychology, Northwestern University, Evanston, IL

### ABSTRACT

We discuss problems the null hypothesis significance testing (NHST) paradigm poses for replication and more broadly in the biomedical and social sciences as well as how these problems remain unresolved by proposals involving modified  $p$ -value thresholds, confidence intervals, and Bayes factors. We then discuss our own proposal, which is to abandon statistical significance. We recommend dropping the NHST paradigm—and the  $p$ -value thresholds intrinsic to it—as the default statistical paradigm for research, publication, and discovery in the biomedical and social sciences. Specifically, we propose that the  $p$ -value be demoted from its threshold screening role and instead, treated continuously, be considered along with currently subordinate factors (e.g., related prior evidence, plausibility of mechanism, study design and data quality, real world costs and benefits, novelty of finding, and other factors that vary by research domain) as just one among many pieces of evidence. We have no desire to “ban”  $p$ -values or other purely statistical measures. Rather, we believe that such measures should not be thresholded and that, thresholded or not, they should not take priority over the currently subordinate factors. We also argue that it seldom makes sense to calibrate evidence as a function of  $p$ -values or other purely statistical measures. We offer recommendations for how our proposal can be implemented in the scientific publication process as well as in statistical decision making more broadly.

# **AMERICAN STATISTICAL ASSOCIATION RELEASES STATEMENT ON STATISTICAL SIGNIFICANCE AND P-VALUES**

*Provides Principles to Improve the Conduct and Interpretation of Quantitative  
Science*

March 7, 2016

The American Statistical Association (ASA) has released a "Statement on Statistical Significance and *P*-Values" with six principles underlying the proper use and interpretation of the *p*-value [<http://amstat.tandfonline.com/doi/abs/10.1080/00031305.2016.1154108#.Vt2XIOaE2MN>]. The ASA releases this guidance on *p*-values to improve the conduct and interpretation of quantitative science and inform the growing emphasis on reproducibility of science research. The statement also notes that the increased quantification of scientific research and a proliferation of large, complex data sets has expanded the scope for statistics and the importance of appropriately chosen techniques, properly conducted analyses, and correct interpretation.

# The Role of Statistical Inference

- Consider a hypothetical population described by random variables  $(x, y)$ . Suppose we fit a simple linear model onto the population:

$$y = \beta x + e \tag{1}$$

Fitting (1)  $\Rightarrow \beta^*$ .

- Now suppose the data we observe,  $\mathcal{D} = \{(x_1, y_1), \dots, (x_N, y_N)\}$ , is a random sample drawn from the population. Fitting (1) onto the observed data gives us  $\hat{\beta}$ .

# The Role of Statistical Inference

- The goal of statistical inference is to form statements about  $\beta^*$  when we can only obtain  $\hat{\beta}$ .
- In other words, statistical inference deals with the problem of uncertainty in our estimates due to **sample variability**.
- It does *not* deal with the problems of
  - ▶ Whether (1) is a good model for predicting  $y$  based on  $x$
  - ▶ Whether  $x$  has any causal effect on  $y$  and whether (1) is a good model for describing the causal effect (if exists)

## Hypothesis Testing: What it is and What it is not

$$\mathbb{H}_0 : \beta^* = 0 \text{ vs. } \mathbb{H}_1 : \beta^* \neq 0$$

Under  $H_0$ ,

$$t(\hat{\beta}) = \frac{\hat{\beta}}{\widehat{se}(\hat{\beta})} \xrightarrow{d} \mathcal{N}(0, 1) \quad (2)$$

$p$ -value:

$$P(\hat{\beta}) = \Pr(|t| \geq |t(\hat{\beta})| \mid \mathbb{H}_0) \quad (3)$$

Based on (2), we can estimate  $P(\hat{\beta})$  as

$$\hat{P}(\hat{\beta}) = 2(1 - \Phi(|t(\hat{\beta})|)) \quad (4)$$

, where  $\Phi$  is the CDF of  $\mathcal{N}(0, 1)$ .

## Hypothesis Testing: What it is and What it is not

The rejection of  $\mathbb{H}_0$  does *not* imply  $|\beta^*|$  is significantly different from 0.

- Even if the rejection is correct, i.e.  $\beta^* \neq 0$ , it could be that  $|\beta^*|$  is small and close to 0.
- To assess the magnitude of  $\beta^*$ , confidence intervals are more useful than  $p$ -values.
  - ▶ E.g., it is more informative to report a confidence interval of, say, [.001, .009] than a  $p$ -value of .0124.

## Hypothesis Testing: What it is and What it is not

The rejection of  $\mathbb{H}_0$  does *not* mean  $x$  has a significant causal effect on  $y$ .

- It is never the case that statistical significance is the same as scientific, real-world significance. The most important variables are *not* those with the smallest p-values.

## Hypothesis Testing: What it is and What it is not

In general, when there are  $p$  predictors, and we are testing the coefficient on  $x_j$ , the null hypothesis is not just " $\mathbb{H}_0 : \beta_j^* = 0$ ", but

$\mathbb{H}_0 : \beta_j^* = 0$  in a linear model that also includes predictors  $x_1, \dots, x_{j-1}, x_{j+1}, \dots, x_p$  and nothing else.

- The  $t$ -test can be thought of as checking whether adding  $x_j$  really improves predictions in a model that contains  $\{x_1, \dots, x_{j-1}, x_{j+1}, \dots, x_p\}$ .
- Of course, adding more predictors never hurts the performance of a model on the training data. The  $t$ -test gauges whether the improvement in prediction is small enough to be due to random sampling.

## Confidence Interval: What it is and What it is not

A 95% confidence interval  $\text{CI} = [\hat{\beta} - 1.96 \cdot \hat{s}\text{e}(\hat{\beta}), \hat{\beta} + 1.96 \cdot \hat{s}\text{e}(\hat{\beta})]$   
does *not* mean that  $\Pr(\beta^* \in \text{this particular CI}) = .95$ .

- Correct interpretation: a 95% confidence interval for  $\beta^*$  means that if we estimate our model on many independent random samples drawn from the same population and construct  $\text{CI}_m = [\hat{\beta}_m - 1.96 \cdot \hat{s}\text{e}(\hat{\beta}_m), \hat{\beta}_m + 1.96 \cdot \hat{s}\text{e}(\hat{\beta}_m)]$  on each sample, then 95% of  $\{\text{CI}_m\}$  will contain  $\beta^*$ .

# The Study and Target Populations

- Researchers often do not specify what the underlying population is that their observed sample is supposed to be drawn from – call it the **study population**, and the **target population** that they are trying to make inference on.
- Without a clear idea of what these populations are, hypothesis testing does *not* make sense.
- Questions we need to answer *before* conducting any analysis:
  - ① What is our study population and what is our target population?
  - ② How is the observed sample generated – is it, for example, a random sample drawn from the study population?

# The Study and Target Populations

nature

OPINION

## Most people are not WEIRD

To understand human psychology, behavioural scientists must stop doing most of their experiments on Westerners, argue **Joseph Henrich, Steven J. Heine and Ara Norenzayan**.

A 2008 survey of the top psychology journals found that 96% of subjects were from Western, educated, industrialized, rich and democratic (WEIRD) societies – particularly American undergraduates.

# Hypothesis Testing and Decision Theory

Let  $\mathbb{H}_1 \in \{0, 1\}$  denote whether  $\mathbb{H}_1$  is false or true and let  $\widehat{\mathbb{H}}_1 \in \{0, 1\}$  denote our decision to reject or accept the hypothesis<sup>1</sup>.

		$\widehat{\mathbb{H}}_1$
		0
0		no error
$\mathbb{H}_1$	0	<b>Type I error</b> (false positive)
	1	no error
1		<b>Type II error</b> (false negative)

Optimal decision should be made based on  $p(\mathbb{H}_1)$  (or equivalently,  $p(\mathbb{H}_0)$ ) and cost function  $\ell(\mathbb{H}_1, \widehat{\mathbb{H}}_1)$ <sup>2</sup>.

<sup>1</sup>i.e.,  $\widehat{\mathbb{H}}_1 = 0$  if we accept  $\mathbb{H}_0$  and reject  $\mathbb{H}_1$ .  $\widehat{\mathbb{H}}_0 = 1$  if we reject  $\mathbb{H}_0$  and accept  $\mathbb{H}_1$ .

<sup>2</sup>For example,

$$\ell(\mathbb{H}_1, \widehat{\mathbb{H}}_1) = \begin{cases} 95 & \mathbb{H}_1 = 0, \widehat{\mathbb{H}}_1 = 1 \\ 5 & \mathbb{H}_1 = 1, \widehat{\mathbb{H}}_1 = 0 \\ 0 & \text{o.w.} \end{cases}$$

leads to a decision rule of  $\widehat{\mathbb{H}}_1 = \mathcal{I}(p(\mathbb{H}_1) > 0.95) = \mathcal{I}(p(\mathbb{H}_0) \leq 0.05)$ .

# P-Value: What it is and What it is not

The  $p$ -value is *not* the conditional probability of  $\mathbb{H}_0$ . When  $p$ -value  $\leq \alpha$ , it does *not* mean that the probability of  $\mathbb{H}_0$  being true, conditional on the observed data (test statistic), is less than  $\alpha$ .

Given observed evidence  $E^3$ ,

$$\begin{aligned}\Pr(\mathbb{H}_0 | E) &= \frac{\Pr(E | \mathbb{H}_0) \Pr(\mathbb{H}_0)}{\Pr(E)} \\ &= \frac{\Pr(E | \mathbb{H}_0) \Pr(\mathbb{H}_0)}{\Pr(E | \mathbb{H}_0) \Pr(\mathbb{H}_0) + \Pr(E | \mathbb{H}_1) \Pr(\mathbb{H}_1)}\end{aligned}$$

---

<sup>3</sup>e.g.,  $E$  is our observed data or test statistic.

# P-Value: What it is and What it is not

- $\Pr(\mathbb{H}_0)$  is the **prior probability** of  $\mathbb{H}_0$  being true, which represents our belief in  $\mathbb{H}_0$  *before* we observe the evidence  $E$ .
- $\Pr(\mathbb{H}_0|E)$  is the **posterior probability** of the  $\mathbb{H}_0$  being true, which represents our belief in  $\mathbb{H}_0$  *after* we observe  $E$ .
- We are interested in making decisions based on  $\Pr(\mathbb{H}_0|E)$ , but  $p$ -value gives us  $\Pr(E|\mathbb{H}_0)$ .
- In particular, if  $\Pr(\mathbb{H}_0)$  is large, then even if  $\Pr(E|\mathbb{H}_0)$  is small,  $\Pr(\mathbb{H}_0|E)$  may not be small<sup>4</sup>.

---

<sup>4</sup>This highlights the limitations of the frequentist approach – inability to incorporate prior knowledge.

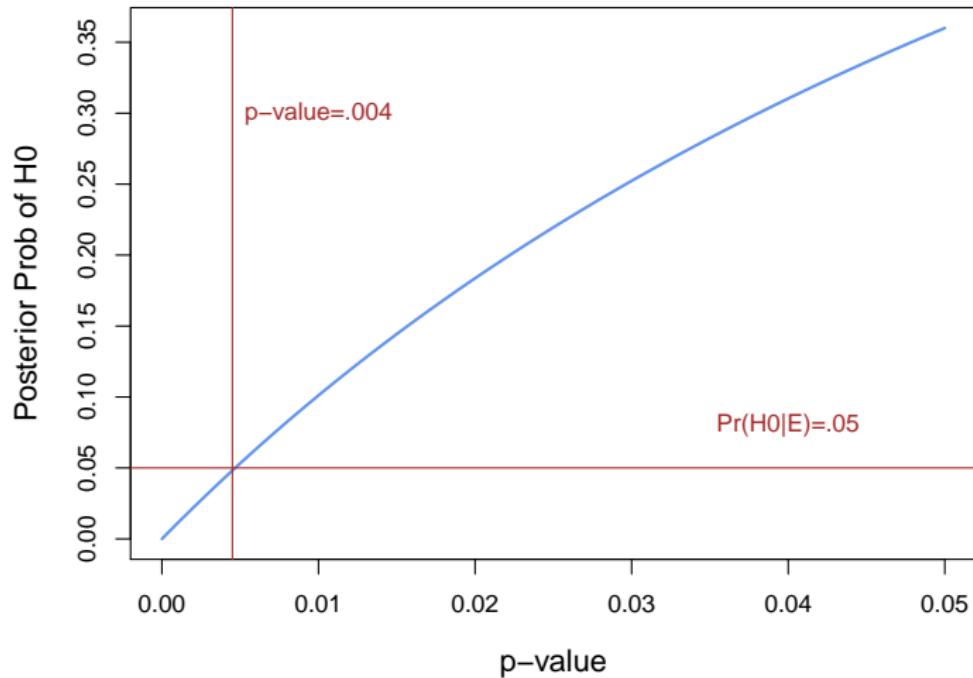

# P-Value: What it is and What it is not

```
# Numerical Example
```

```
p_H0 <- .9 # Pr(H0)
p_H1 <- 1 - p_H0 # Pr(H1)
p_E_H0 <- seq(.01, .05, by = .01) # Pr(E/H0), i.e. p-value
p_E_H1 <- .8 # Pr(E/H1)
p_H0_E <- (p_E_H0*p_H0)/(p_E_H0*p_H0 + p_E_H1*p_H1) # Pr(H0/E)
p_H0_E

## [1] 0.1011236 0.1836735 0.2523364 0.3103448 0.3600000
```

# P-Value: What it is and What it is not

# P-Value: What it is and What it is not

The  $p$ -value can be interpreted as the probability of  $\mathbb{H}_0$  being true based *only* on the observed data set (without incorporating prior knowledge).

## Moral

When the alternative hypothesis is highly unlikely based on prior belief (say,  $\Pr(\mathbb{H}_1) < 0.1$ ), we may need the  $p$ -value to be much smaller than the conventional threshold of  $\alpha = .05$  in order to “confidently” reject  $\mathbb{H}_0$ <sup>a,b,c</sup>

---

<sup>a</sup>That is, we want to reject  $\mathbb{H}_0$  when  $\Pr(\mathbb{H}_0|E)$  is small, according to our decision cost function.

<sup>b</sup>In other words,  $\alpha$  should ideally be a function of  $\Pr(\mathbb{H}_0)$  rather than a constant.

<sup>c</sup>or we can just go Bayesian!

# Journal's Paper on ESP Expected to Prompt Outrage

By BENEDICT CAREY

Published: January 5, 2011

One of psychology's most respected journals has agreed to publish a paper presenting what its author describes as strong evidence for extrasensory perception, the ability to sense future events.

 [Enlarge This Image](#)

Heather Ainsworth for The New York Times

Work by Daryl J. Bem on extrasensory perception is scheduled to be published this year.

The decision may delight believers in so-called paranormal events, but it is already mortifying scientists. Advance copies of the [paper](#), to be published this year in *The Journal of Personality and Social Psychology*, have circulated widely among psychological researchers in recent weeks and have generated a mixture of amusement and scorn.

The paper describes nine unusual lab experiments performed over the past decade by its author, [Daryl J. Bem](#), an emeritus professor at Cornell, testing the ability of college students to accurately sense random events,

## P-Value and Sample Size

- When  $N$  is small, the power of the test – the probability of correctly rejecting  $\mathbb{H}_0$  – is low. At the same time, (4) can be a poor estimator for  $P(\hat{\beta})$ , since it is based on the asymptotic distribution of  $t(\hat{\beta})$ .<sup>5,6</sup>
- When  $N$  is very large ( $N \rightarrow \infty$ ),  $\hat{\beta}$  converges to  $\beta^*$ : no need for hypothesis testing.<sup>7</sup>.

---

<sup>5</sup>The exact distribution of the  $t$ -statistic in finite samples can be derived under additional distributional assumptions. For example, if we assume a linear normal model

$$y = x'\beta + e, \quad e \sim \mathcal{N}(0, \sigma^2)$$

Then  $t(\hat{\beta}_j) \sim t_{n-p-1}$ , where  $x$  is  $(p+1)$  dimensional. However, the assumptions of the linear normal model – gaussianity, homoskedasticity, and error independence – are seldomly satisfied.

<sup>6</sup>In this case one can sometimes use bootstrapping to obtain more accurate  $p$ -value estimates.

<sup>7</sup>In other words, hypothesis tests based on the asymptotic properties of test statistics are valid for large samples, but only useful for samples that are not too large.

# P-Value and Sample Size

## Moral

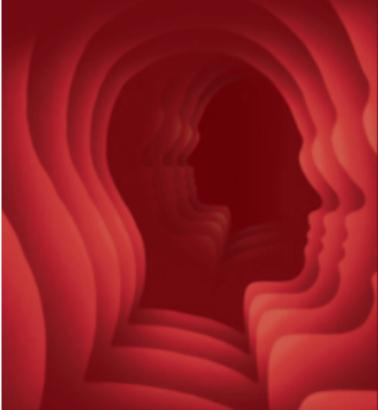

Do not trust the  $p$ -values calculated on small samples!

*"The concept of  $p$ -values was originally developed by statistician Ronald Fisher in the 1920s in the context of his research on crop variance in Hertfordshire, England. Fisher offered the idea of  $p$ -values as a means of protecting researchers from declaring truth based on patterns in noise. In an ironic twist,  $p$ -values are now often used to lend credence to noisy claims based on small samples."* – Gelman and Loken (2014)

### [Turning Body and Self Inside Out: Visualized Heartbeats Alter Bodily Self-Consciousness and Tactile Perception](#)

*Jane Elizabeth Aspell, Lukas Heydrich, Guillaume Marillier, Tom Lavanchy, Bruno Herbelin, and Olaf Blanke*

Studies of body perception have mostly focused on manipulations of exteroceptive cues (e.g., vision and touch); however, interoceptive cues (i.e., representations of internal bodily states) may be just as important for self-perception. Participants viewed a virtual body or a rectangle, each of which had a flashing outline that was synchronous or asynchronous with the participant's own heartbeat. Self-identification was stronger for people viewing the virtual body with the synchronous flashing outline than for those viewing the body with the asynchronous flashing outline or for those viewing the rectangles. This suggests that both interoceptive and exteroceptive cues play important roles in bodily self-perception.

### [Aging 5 Years in 5 Minutes: The Effect of Taking a Memory Test on Older Adults' Subjective Age](#)

*Matthew L. Hughes, Lisa Geraci, and Ross L. De Forrest*

Subjective age -- how old people feel -- is related to psychological and physical well-being. In this study, the researchers examined whether common memory-testing procedures influence adults' subjective age. Older and younger adults rated their subjective age before and after taking a memory test. Older adults reported feeling older after taking the memory test, but younger adults did not. A follow-up study found that

# The Information Content of Statistical (Non)Significance

- A statistical result is **informative** when it has the potential to substantially change our beliefs.
- The discrepancy between a prior and a posterior distribution thus provides a basic measure of the informativeness of a statistical result.
- Using this measure, nonsignificant results are often *more* informative than significant results in scenarios common in empirical economics.

# The Information Content of Statistical (Non)Significance

- Unlike in the medical sciences, in empirical economics, for most parameter  $\theta$  that we are interested in, there are rarely reasons to put substantial prior probability on the point null  $\mathbb{H}_0 : \theta = 0$ .
  - ▶ Beliefs on the causal effect of a policy intervention are usually better described by a continuous distribution rather than a distribution with significant probability mass at point zero.
- When  $\Pr(\mathbb{H}_0)$  is small, statistical significance often carries little information, while nonsignificance is highly informative, because in this case, nonsignificance is more “surprising” and induces a larger change in the posterior belief.

# The Information Content of Statistical (Non)Significance

Suppose we are given a sample  $\mathcal{D} = \{x_i\}_{i=1}^N$  and a probabilistic model  $x_i \stackrel{i.i.d.}{\sim} \mathcal{N}(\theta, 1)$ . Then

$$\hat{\theta} = \frac{1}{N} \sum_{i=1}^N x_i \sim \mathcal{N}\left(\theta, \frac{1}{N}\right)$$

Let  $E \doteq \mathcal{I}\left(\sqrt{N}|\hat{\theta}| > 1.96\right)$ .  $\theta$  is statistically significant at the 5% level if  $E = 1$ .

# The Information Content of Statistical (Non)Significance

Our prior regarding  $\theta$  is  $\theta \sim \mathcal{N}(\mu, \sigma^2)$ . Given this prior, we can compute the limited-information posterior<sup>a</sup>  $p(\theta | E = 0)$  and  $p(\theta | E = 1)$ <sup>b</sup>.

---

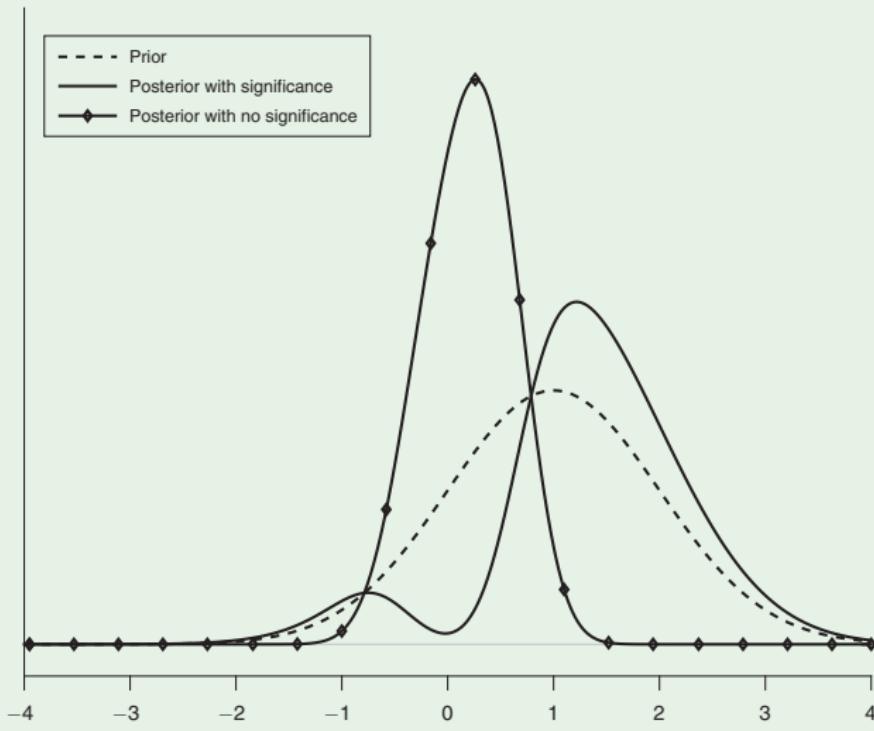

<sup>a</sup>Limited-information posterior:  $p(\theta | E)$ . Full-information posterior:  $p(\theta | \mathcal{D})$

<sup>b</sup>

$$p(\theta | E = 1) = \frac{\frac{1}{\sigma} \phi\left(\frac{\theta - \mu}{\sigma}\right) [\Phi(\sqrt{N}\theta - c) + \Phi(-\sqrt{N}\theta - c)]}{\Phi\left(\frac{\sqrt{N}\mu - c}{\sqrt{1+N\sigma^2}}\right) + \Phi\left(\frac{-\sqrt{N}\mu - c}{\sqrt{1+N\sigma^2}}\right)}$$

, where  $c = 1.96$  is the critical value at the 5% significance level. See Abadie (2020).

# The Information Content of Statistical (Non)Significance

Panel D.  $n = 10,000$

--- Prior — Posterior

$p(\theta)$  and  $p(\theta|E = 1)$ . Abadie (2020)

© Jiaming Mao

# The Information Content of Statistical (Non)Significance

Given parameter of interest  $\theta$  and prior belief  $p(\theta)$ , let  $E \in \{0, 1\}$  denote whether  $\mathbb{H}_0 : \theta = 0$  is rejected at a given significance level.

$$p(\theta) = p(\theta|E=0)\Pr(E=0) + p(\theta|E=1)\Pr(E=1)$$

$\Rightarrow$

$$\underbrace{\left|1 - \frac{p(\theta|E=0)}{p(\theta)}\right|}_{\text{informativeness of nonsignificance}} = \left(\frac{\Pr(E=1)}{\Pr(E=0)}\right) \underbrace{\left|1 - \frac{p(\theta|E=1)}{p(\theta)}\right|}_{\text{informativeness of significance}}$$

- Nonsignificance is more informative than significance as long as  $\Pr(E=1)$  – the prior probability of rejection of the null – is greater than 0.5.

# The Information Content of Statistical (Non)Significance

$$\Pr(E = 1) = \int \Pr(E = 1|\theta) p(\theta) d\theta$$

, where for  $\theta \neq 0$ ,  $\Pr(E = 1|\theta)$  is the power of the test.

- $N \uparrow$  and  $p(\theta = 0) \downarrow \Rightarrow \Pr(E = 1) \uparrow$ . Thus, as data sets get larger, and because there are rarely reasons to put significant priors on  $\theta = 0$ , nonsignificant results will often be more informative in empirical studies in economics.
- In the extreme, when  $N$  is very large, without prior probability mass at the point null, significance carries no information.

# The Information Content of Statistical (Non)Significance

Moral (Abadie, 2020)

- We advocate visible reporting and discussion of nonsignificant results in empirical practice.
- The weight of statistical evidence should not be primarily assessed on the basis of statistical significance. Other factors, such as the magnitude and precision of the estimates, the plausibility and novelty of the results, and the quality of the data and research design, should be carefully evaluated alongside discussions of statistical significance or of the magnitude of p-values.

## More Problems with the Use of P-Values in Practice

- The Statistical Significance Filter (Publication Bias)
- P-Hacking (Data Snooping)

# The Statistical Significance Filter

- Focusing on statistically significant results is an entrenched culture in scientific research and publishing: only significant results get published. Consequently, published empirical findings are not a representative sample of all empirical findings.
- This is called the **statistical significance filter** or **publication bias**.

# The Statistical Significance Filter

Suppose  $\beta^*$  is unbiasedly estimated by  $\hat{\beta} \sim \mathcal{N}(\beta^*, 1)$ . If we only consider statistically significant results (at the 5% level), then we will only consider cases in which  $|\hat{\beta}| > 1.96$ .

- $E[|\hat{\beta}| | |\hat{\beta}| > 1.96]$  is clearly an overestimate of  $|\beta^*|$ .
- In particular, if  $|\beta^*| < 1.96$ , then any statistically significant  $\hat{\beta}$  will *always* be too high in magnitude.

# The Statistical Significance Filter

- Simulation: draw  $M = 100$  random samples, each containing  $N = 200$  data points, from the following population:

$$\begin{aligned}x &\sim \text{Bernoulli}(0.5) \\y &\sim \mathcal{N}(1 + 0.1x, 1)\end{aligned}\tag{5}$$

- Given (5), we have:

$$y = \alpha^* + \beta^*x + e^*\tag{6}$$

where  $\alpha^* = 1, \beta^* = 0.1$ .

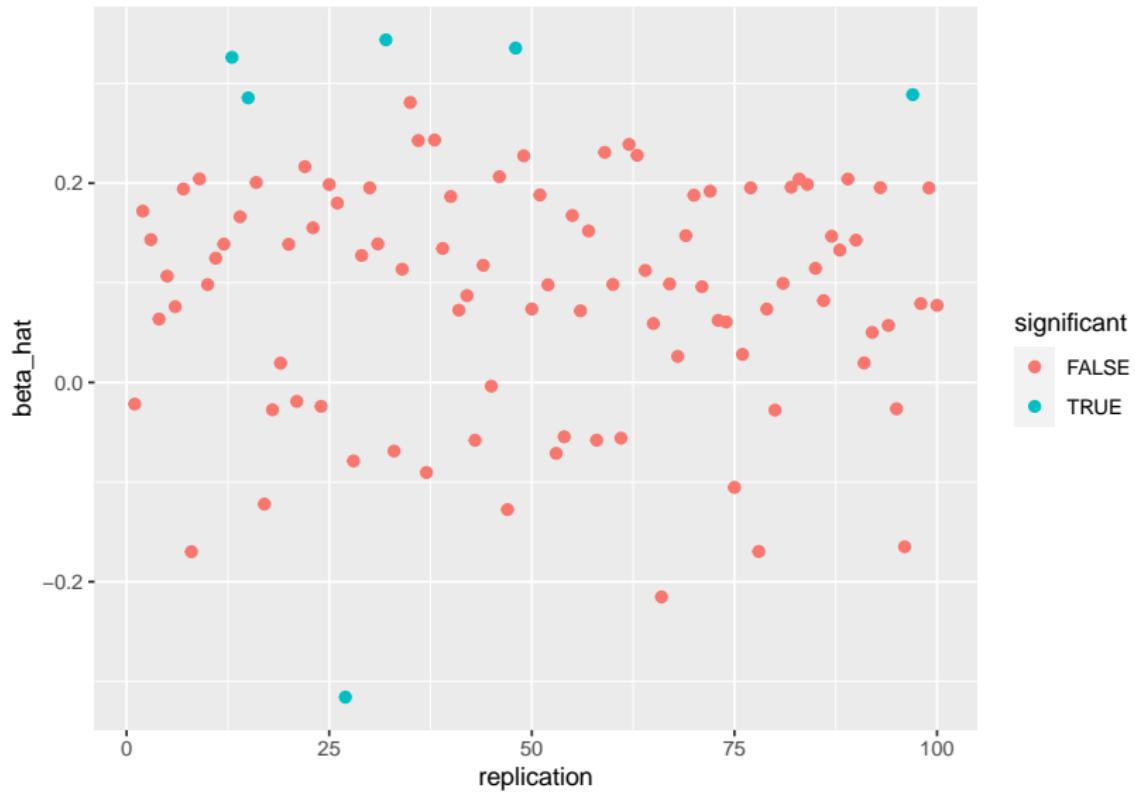

- Run regression on each data set  $m$  and obtain the OLS estimator  $\hat{\alpha}_m, \hat{\beta}_m$ .

# The Statistical Significance Filter

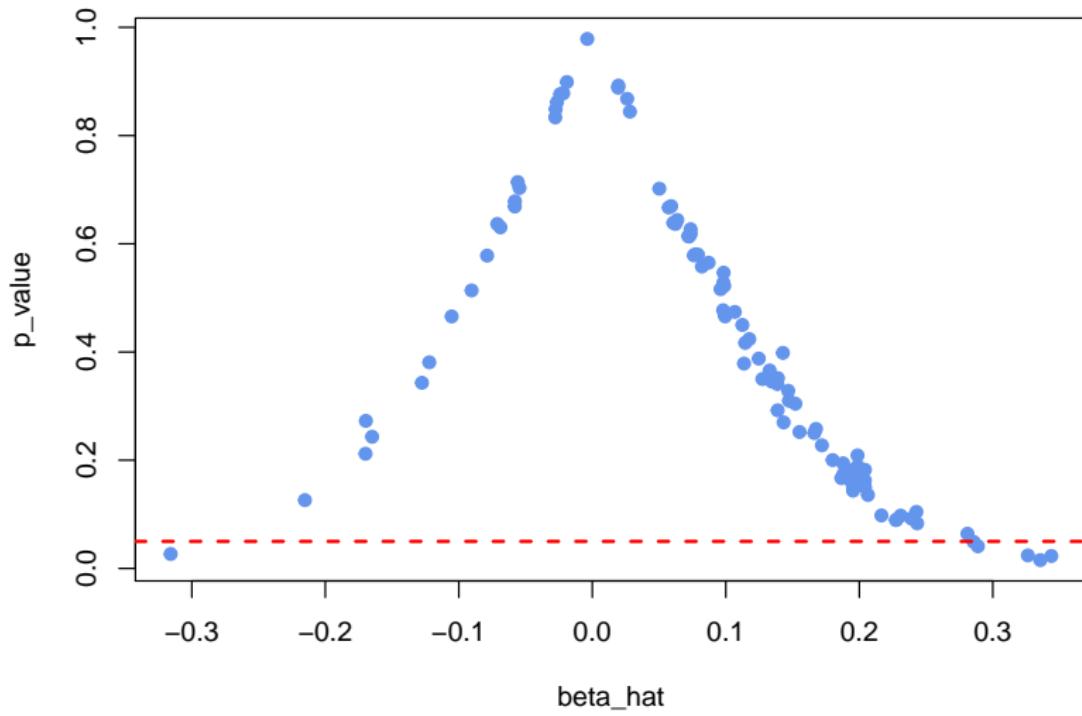

```
# Simulation
require(dplyr)
require(broom)
M <- 100
N <- 200
beta_hat_dist <- replicate(M, {
  x <- rbinom(N, 1, 0.5)
  y <- 1 + 0.1 * x + rnorm(N)
  fit <- lm(y ~ x)
  coef <- tidy(fit) %>% filter(term == "x")
  c(beta_hat = coef$estimate, p_value = coef$p.value)
})
# E(beta_hat)
beta_hat_dist <- as.data.frame(t(beta_hat_dist))
beta_hat_dist %>% summarise (e_beta_hat = mean(beta_hat))

# Evidence of Publication Bias

Results from Open Science Collaboration (2015). Plot taken from Andrews and Kasy (2019).

# Moral

## McShane et al. (2019)

- We propose that the p-value be demoted from its threshold screening role and instead, treated continuously.

## Kenkel (2016)

- Assume the magnitudes of published results are exaggerated and adjust our own beliefs accordingly.
- Collect new data to replicate published findings and adjust our beliefs in the direction of the replication results.

## Open Science Collaboration (2015)

- Deciding the ideal balance of resourcing innovation versus verification is a question of research efficiency. How can we maximize the rate of research progress? Innovation points out paths that are possible; replication points out paths that are likely; progress relies on both. The ideal balance is a topic for investigation itself. Scientific incentives—funding, publication, or awards—can be tuned to encourage an optimal balance in the collective effort of discovery.

# In Search of Statistical Significance

Many specifications in search of statistical significance. [Source.](#)

# In Search of Statistical Significance

One specification (here: Sir Perceval) achieves statistical significance. [Source](#).

# In Search of Statistical Significance

- The best practice for data analysis is to fix the model **before** seeing the training data and keep a separate test data set for assessing the performance of the estimated model.
- In practice, however, many researchers will try many specifications **after** seeing the data, until they get their desired, i.e. statistically significant, results.
- Some will also manipulate the data collection and processing stage by, for example, estimating a model on different subsets of the data in search of statistical significance, or stop data collection as soon as  $p < 0.05$ .

# In Search of Statistical Significance

- Indeed, a dataset can be analyzed in many different ways, with the choices being not just what models to use, but also decisions on what measures to study, what data to include or exclude, etc.<sup>8</sup>, that it can be easy to find a statistically significant result even if nothing is going on, as long as you look hard enough.

*"If you torture the data long enough, it will confess."* – Ronald Coase

- Such practices of *data-dependent analyses* are called ***p*–hacking** or ***data snooping***<sup>9</sup>.

---

<sup>8</sup>This has been called the “researcher degrees of freedom.”

<sup>9</sup>Also called specification search, data dredging, fishing . . . – you get the idea.

# In Search of Statistical Significance

*"If you don't reveal some insights soon, I'm going  
to be forced to slice, dice, and drill!"*

# Multiple Testing

- The problems of  $p$ -hacking are essentially the problems of **multiple testing** (also called **multiple comparisons**).
- If you perform multiple hypothesis tests, the probability of at least one producing a statistically significant result at the significance level  $\alpha$  *purely due to chance*, is necessarily greater than  $\alpha$ .
- Assuming each test is independent, under the  $H_0$  of all tests,

$$\Pr(\text{at least one is (falsely) positive}) = 1 - (1 - \alpha)^n$$

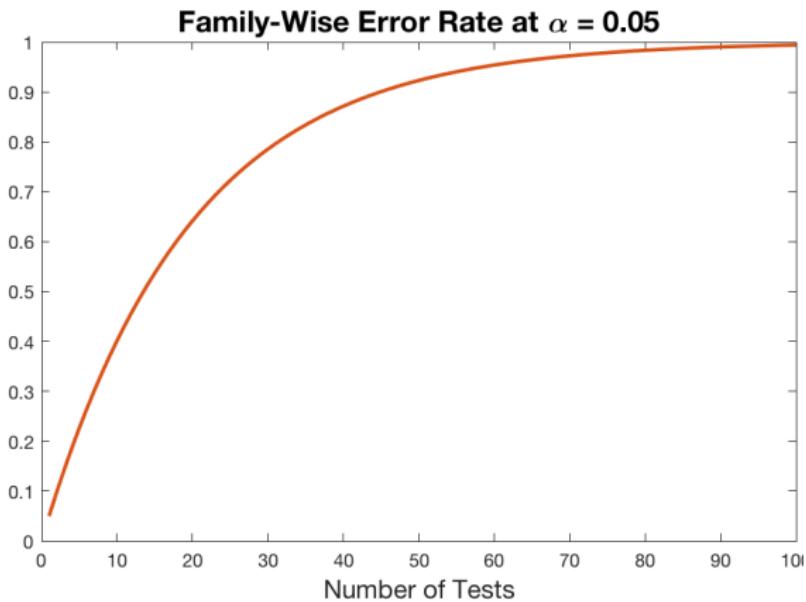

, where  $n$  is the number of tests conducted<sup>10</sup>.

---

<sup>10</sup>Try Jerry Dallal's demo: [100 Independent 0.05 Level Tests For An Effect Where None Is Present](#).

# Multiple Testing

$N$	$\Pr(\text{false positive})$
1	0.05
2	0.0975
5	0.2262
10	0.4013
50	0.9231
100	0.9941

## Multiple Testing

*"Recognize that any frequentist statistical test has a random chance of indicating significance when it is not really present. Running multiple tests on the same data set at the same stage of an analysis increases the chance of obtaining at least one invalid result. Selecting the one "significant" result from a multiplicity of parallel tests poses a grave risk of an incorrect conclusion. Failure to disclose the full extent of tests and their results in such a case would be highly misleading." – Professionalism Guideline 8, Ethical Guidelines for Statistical Practice, American Statistical Association, 1997*

# Ovulation and Voting

*Psychol Sci.* 2013 Jun;24(6):1007-16. doi: 10.1177/0956797612466416. Epub 2013 Apr 23.

## The fluctuating female vote: politics, religion, and the ovulatory cycle.

Durante KM<sup>1</sup>, Rae A, Griskevicius V.

### Author information

#### Abstract

Each month, many women experience an ovulatory cycle that regulates fertility. Although research has found that this cycle influences women's mating preferences, we proposed that it might also change women's political and religious views. Building on theory suggesting that political and religious orientation are linked to reproductive goals, we tested how fertility influenced women's politics, religiosity, and voting in the 2012 U.S. presidential election. In two studies with large and diverse samples, ovulation had drastically different effects on single women and women in committed relationships. Ovulation led single women to become more liberal, less religious, and more likely to vote for Barack Obama. In contrast, ovulation led women in committed relationships to become more conservative, more religious, and more likely to vote for Mitt Romney. In addition, ovulation-induced changes in political orientation mediated women's voting behavior. Overall, the ovulatory cycle not only influences women's politics but also appears to do so differently for single women than for women in relationships.

## Ovulation and Voting

Sample: participants were 275 women with a mean age of 27.95 years (SD = 6.05, range = 18–44 years) who had regular monthly menstrual cycles (25–35 days) and were not using hormonal contraception.

Fertility: we created a high-fertility group (cycle days 7–14, n = 78) and a low- fertility group (cycle days 17–25, n = 85). For our main analyses, we did not include women on cycle days 15 and 16 ... We also did not include women at the beginning of the ovulatory cycle (cycle days 1–6) or at the end of the ovulatory cycle (cycle days 26–28).

Relationship status: participants who indicated that they were engaged, living with a partner, or married were classified as being in a committed relationship (n = 82); all others (e.g., not dating or dating) were classified as single (n = 81).

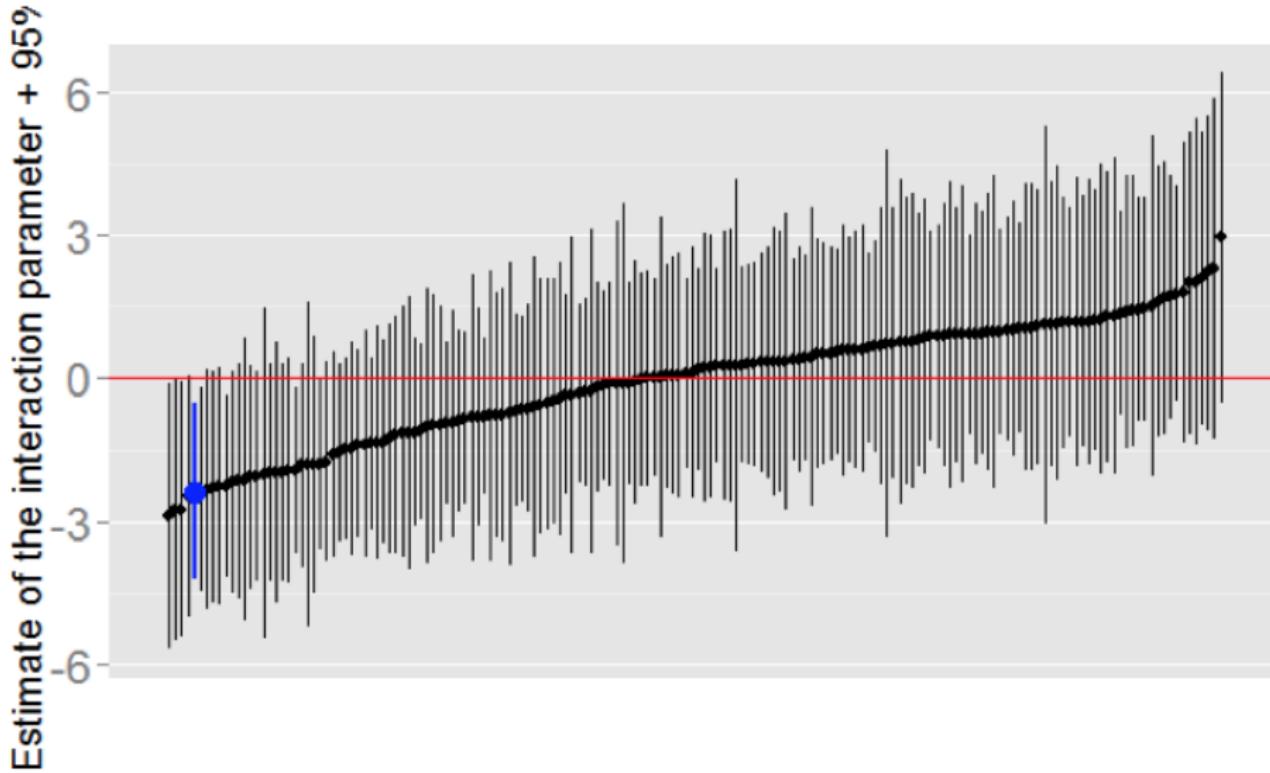

# Ovulation and Voting

Researcher degrees of freedom:

- Exclusion criteria based on cycle length (3 options)
- Exclusion criteria based on “How sure are you?” response (2)
- Cycle day assessment (3)
- Fertility assessment (4)
- Relationship status assessment (3)

Altogether: 168 possibilities

Harris and Mickes (2014): “We attempted to directly replicate the findings of Durante et al. ... We unequivocally failed to confirm two of the three key findings from the research reported by Durante et al. ... This study adds to a growing number of failures to replicate several menstrual cycle effects on preferences and attraction ... which invites concerns that this literature as a whole may have a false-positive rate well above the widely presumed 5%.”

## Neural correlates of interspecies perspective taking in the post-mortem Atlantic Salmon: An argument for multiple comparisons correction

### INTRODUCTION

With the extreme dimensionality of functional neuroimaging data comes extreme risk for false positives. Across the 130,000 voxels in a typical fMRI volume the probability of a false positive is almost certain. Correction for multiple comparisons should be completed with these datasets, but is often ignored by investigators. To illustrate the magnitude of the problem we carried out a real experiment that demonstrates the danger of not correcting for chance properly.

### METHODS

Subject. One mature Atlantic Salmon (*Salmo salar*) participated in the fMRI study. The salmon was approximately 18 inches long, weighed 3.8 lbs, and was not alive at the time of scanning.

### GLM RESULTS

A *t*-contrast was used to test for regions with significant BOLD signal change

Bennett, et al. (2009)

# The Bonferroni Correction

- The probability of making at least one type I error when simultaneously performing  $n$  hypothesis tests is called the **joint type I error rate**, also called the **family-wise error rate (FWER)**.
- The Bonferroni correction bounds the FWER at below  $\alpha$  by setting the significance threshold for each individual test at  $\alpha/n^{11}$ :

$$1 - \left(1 - \frac{\alpha}{n}\right)^n \leq \alpha$$

- The Bonferroni correction is *conservative*: it is derived under the assumption of independent tests. Using the Bonferroni correction when the number of tests is large leads to a significant loss of power<sup>12</sup>.

---

<sup>11</sup>For example, if 10 hypothesis tests are performed, then the Bonferroni corrected significance level is 0.005 for each individual test in order for the FWER at below 0.05.

<sup>12</sup>Recall that power  $\downarrow$  as  $\alpha \downarrow$ . Thus while the Bonferroni correction reduces the number of false positive findings, it does so at the expense of our ability to reject the null when it should have been.

## Data Snooping

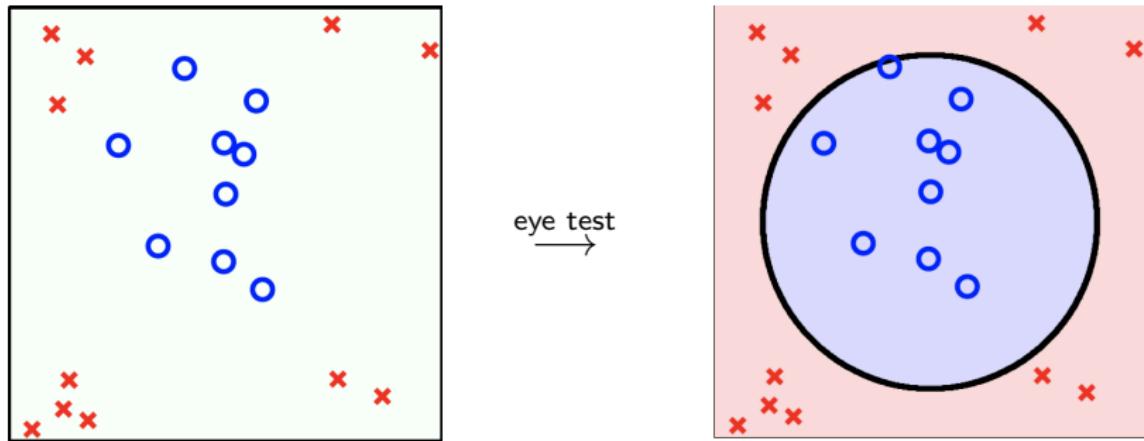

More generally, we have the following principle:

If a data set has affected any step in the learning process, it cannot be fully trusted in assessing the outcome.

- Choosing a model based on the particular features of a data set invalidates the VC generalization bounds calculated based on the VC dimension of the final estimated model.
- If your approach is to try a series of models on your data set before choosing one, then the *effective* VC dimension should be the VC dimension of the entire union of models that you would consider in this specification search process.

# Data Snooping

The specification search process doesn't have to be explicit. Sometimes we do this in our head by *looking* at the data before choosing a model. Doing so is also an act of data snooping.

# Data Snooping

- In general, the more we are willing to let a particular data set dictate our model choice, the poorer our result will generalize out of sample.
- The smaller the sample size, the more data snooping is a problem. When the sample size is large, multiple testing and data snooping are less of a concern, as  $N \uparrow \Rightarrow$  generalization bound for  $|E_{out} - E_{in}| \downarrow$ .

## Data Snooping

- A type of data snooping that is more difficult to avoid involves the reuse of the same data set by different people. This occurs, for example, when researchers work on the same public data set.
- When working with a public data set, it is common for a researcher to read about what others have done using the same data before formulating her model. In doing so, her model choice is already affected by the data set, since it is based what others have shown to work well or not well on *that particular* data set.

# Data Snooping

- When researchers work on the same data set, while each formulating new hypotheses based on the work of others, the *effective* VC dimension corresponds to a much larger model space than the model chosen by any individual researcher – the model space contains all hypotheses that have been considered (and mostly rejected) by every researcher in this adaptive analysis process.
- This is a particular problem for social scientific research, where the ability to generate new data is limited, and many, mutually dependent, studies are based on the same datasets<sup>13</sup>.

---

<sup>13</sup>This partly explains why social science models tend to have poorer generalization ability (predictive power) than natural science models.

# Moral

## When reading others' research...

- Be aware of the multiple testing and data snooping that might have been going on behind published results, and adjust our beliefs about their generalization performance accordingly.
- Be aware of the inherent data snooping problem in adaptive analysis when reading published results based on data sets that have been used by many others, and adjust our beliefs about their generalization performance accordingly.

# Moral

## When conducting your own research...

- Formulate the research question and decide on what model to use *before* seeing the data.
  - ▶ If possible, generate new data based on your research design.
- If you *intend* to engage in data snooping and choose a model based on the data, then you should decide on the *set* of models you are going to choose from *before* seeing the data, and account for the data snooping in your analysis by
  - ▶ Adjusting the significance level of your hypothesis tests by, for example, using the Bonferroni correction;
  - ▶ Using a test data set to evaluate the performance of your final estimated model. The test set should be allocated at the beginning and only used at the end. Once a data set has been used, it should be treated as *contaminated* as far as testing the performance is concerned.

# Moral

## When reporting your research...

- Aim for honesty and transparency.
- Clearly state your research question, the research design, and the reasoning behind your model choice.
- Clearly state if your analysis involves data snooping and how you have accounted for it.
- Report every hypothesis test you have performed relevant to the research question and highlight results that are robust across tests.
- Include a limitations section and point out any limitations and uncertainties in the analysis.

# Appendix: The ASA Statement on P-Values

## The ASA Statement on P-Values

- ①  $p$ -values can indicate how incompatible the data are with a specified statistical model.
- ②  $p$ -values do not measure the probability that the studied hypothesis is true, or the probability that the data were produced by random chance alone.
- ③ Scientific conclusions and business or policy decisions should not be based only on whether a  $p$ -value passes a specific threshold.
- ④ Proper inference requires full reporting and transparency.
- ⑤ A  $p$ -value, or statistical significance, does not measure the size of an effect or the importance of a result.
- ⑥ By itself, a  $p$ -value does not provide a good measure of evidence regarding a model or hypothesis.
